Let  $\mathbf{X} = \{x_{n,m}\}$  be a matrix of size  $N \times M \rightarrow$  **the image**

We assume that  $x_{n,m} \in \mathbb{R} \rightarrow$  **the pixels**

The image is seen as a vector of  $NM$  dimensions in which the dimensions are arranged with a specific geometry (*i.e.*, a 2D grid of size  $N \times M$ ).

The image  $\mathbf{X}$  can be seen as the sum of each pixel

And as a linear combination of the **Pixel-basis**

In this basis, the position of the pixels is not taken into account, while, it is known that neighboring pixels are generally correlated.

A transform is simply **another basis**  $\{\mathbf{U}_u\}_{u \in \llbracket 0, NM-1 \rrbracket}$ :

$$\mathbf{X} = \hat{x}_0 \mathbf{U}_0 + \dots + \hat{x}_u \mathbf{U}_u + \dots + \hat{x}_{NM-1} \mathbf{U}_{NM-1}$$

in which

- the "2D grid" shape of the image is taken into account
- the representation is sparse (*i.e.*, the number of non-zero  $\hat{x}_u$  is small)
- the representation is more suited for processing (*e.g.*, analysis, filtering, denoising)

From the output of the Fourier transform, we define:

- The frequency spectrum:  $Real(\hat{x}(\omega)) + iImg(\hat{x}(\omega))$   
The Fourier transform of a function produces a frequency spectrum which contains all of the information about the original signal, but in a different form.
- Magnitude spectrum:  $|Real(\hat{x}(\omega)) + iImg(\hat{x}(\omega))|$
- Phase spectrum:  $Arctg\left(\frac{Img(\hat{x}(\omega))}{Real(\hat{x}(\omega))}\right)$
- Power spectrum:  $Real(\hat{x}(\omega))^2 + Img(\hat{x}(\omega))^2$

$$\int_{-\infty}^{+\infty} |x(t)|^2 dt = \int_{-\infty}^{+\infty} |\hat{x}(\omega)|^2 d\omega$$

This formula (**Parseval's theorem or energy conservation**) proves that the energy is conserved by the Fourier transform.

Loosely, the sum (or integral) of the square of a function is equal to the sum (or integral) of the square of its transform.

# Fourier transformation

## Transforms

T. Maugey

What is a transform?

2D Fourier transform

2D Discrete Cosine transform

Wavelet Transform

Graph Transform

Dictionaries

References

- Translation in time/space domain:  $x(t - t_0) \xrightarrow{\mathcal{F}} e^{-2i\pi\omega t_0} \hat{x}(\omega)$

$$x(t - t_0) \xrightarrow{\mathcal{F}} \int_{-\infty}^{+\infty} x(t - t_0) e^{-2i\pi\omega t} dt$$

$$k = t - t_0$$

$$x(t - t_0) \xrightarrow{\mathcal{F}} \int_{-\infty}^{+\infty} x(k) e^{-2i\pi\omega(k+t_0)} dk$$

$$x(t - t_0) \xrightarrow{\mathcal{F}} e^{-2i\pi\omega t_0} \left[ \int_{-\infty}^{+\infty} x(k) e^{-2i\pi\omega k} dk \right]$$

Displacement in time or space induces a **phase shift** proportional to frequency and to the amount of displacement.

- Frequency shift:  $x(t) e^{\pm 2i\pi\omega_0 t} \xrightarrow{\mathcal{F}} \hat{x}(\omega \pm \omega_0)$

Displacement in frequency multiplies the time/space function by a unit phasor which has angle proportional to time/space and to the amount of displacement. Amplitude modulation.

The transform is said “discrete” when:

- the function  $x$  is finite:  $\mathbf{x} = (x(n))_{n \in \llbracket 0, N-1 \rrbracket}$
- the frequencies  $\omega$  are finite  $(\frac{u}{N})_{u \in \llbracket 0, N-1 \rrbracket}$

The 1D DFT is defined by

$$\forall u \in \llbracket 0, N-1 \rrbracket, \quad \hat{x}(u) = \sum_{n=0}^{N-1} x(n) e^{-2i\pi \frac{u}{N} n}$$

The inverse transform is

$$\forall n \in \llbracket 0, N-1 \rrbracket, \quad x(n) = \frac{1}{N} \sum_{u=0}^{N-1} \hat{x}(u) e^{2i\pi \frac{u}{N} n}$$

The DFT transforms a complex signal into its complex spectrum. However, if the signal is real as in most of the applications, half of the data is **redundant**:

- In time domain: the imaginary part of the signal is all zero;
- In frequency domain: the real part of the spectrum is even symmetric and imaginary part odd.

How to avoid this high redundancy? We would need a real unitary transform that transforms a sequence of real data points into its real spectrum.

Fourier transform correlates the signals with a family of waveforms that are well localized in frequency (but nothing in time):

$$\hat{x}(\omega) = \int_{-\infty}^{+\infty} x(t)e^{-2i\pi\omega t} dt$$

To be able to examine the properties of a signal in a time (or space)-frequency domain, a trade-off between the two representations must be found.

How to define a transform that correlates the signal with a family of waveforms that are well concentrated in time (or space) and in frequency?

Can we construct a function well localized in time and frequency?

- Dirac  $\delta_T$ :
  - well localised in time  $t = T$ ;
  - $\hat{\delta}_T(\omega) = e^{-2i\pi\omega T}$ , energy uniformly spread over all frequencies.
- Time scaling:  $x_s(t) = \frac{1}{\sqrt{s}}x(\frac{t}{s})$ ,  $s > 1$ .
  - we gain in time localization;
  - $\hat{x}_s(\omega) = \sqrt{s}\hat{x}(sf)$ , the Fourier transform is dilated.

## Heisenberg uncertainty principle

In quantum mechanics, the Heisenberg uncertainty principle states that certain pairs of physical properties, like position and momentum, cannot both be known to **arbitrary** precision.

That is, **the more precisely one property is known, the less precisely the other can be known.**

Time and frequency energy concentrations are then restricted by this principle.

If  $f$  is  $\mathcal{L}^2$ , then its time root deviation  $\sigma_t$  and its Fourier root deviation  $\sigma_f$  are defined. Then the Heisenberg uncertainty principle states that

$$\sigma_t^2 \sigma_\omega^2 \geq \frac{1}{4\pi}$$

- $\sigma_t$  is the standard deviation of the function in the temporal domain;
- $\sigma_\omega$  is the standard deviation of the function in the frequency domain.

# Uncertainty principle

## Transforms

T. Maugey

What is a transform?

2D Fourier transform

2D Discrete Cosine transform

Wavelet Transform

Graph Transform

Dictionaries

References

$$\sigma_t^2 \sigma_\omega^2 \geq \frac{1}{4\pi}$$

It means that there is no finite energy function which is compactly supported both in the time and frequency domains.

Example for Fourier:

- $\sigma_t \rightarrow +\infty$  (constant),  $\sigma_\omega \rightarrow 0$  ;
- $\sigma_\omega \rightarrow +\infty$ ,  $\sigma_t \rightarrow 0$  (Dirac).

The windowed Fourier transform replaces the Fourier transform's sinusoidal wave by the product of a sinusoid and a window which is localized in time. The windowing can be used **to divide the signal in small pieces**, and transform them separately. It takes two arguments: time and frequency.

2D Fourier transform

2D Discrete Cosine transform

Wavelet Transform

Graph Transform

Dictionaries

References

Gabor defined in 1946 a new decomposition using a spatial window in the Fourier integral. The window is translated along the spatial axis in order to cover the whole signal.

At a position  $t_0$  and for a frequency  $\omega_0$ , the windowed Fourier transform of a function  $x(t)$  ( $\in L^2(\mathbb{R})$ ) is defined by

$$Sx(\omega_0, t_0) = \int_{-\infty}^{+\infty} x(t) \underbrace{g(t - t_0)}_{\text{Spatial window}} e^{-2i\pi\omega_0 t} dt$$

It measures locally, around the point  $t_0$ , the amplitude of the sinusoidal wave component of frequency  $\omega_0$ .

Originally, the window function  $g(t)$  is a Gaussian (Gabor transform). However, different windows can be used: rectangle, Hamming, Blackman... The resolution in time and frequency of the windowed Fourier transform depends on the spread of the window in time and frequency.

# Windowed Fourier Transform

The continuous wavelet transform of a function  $x(t) (\in L^2\mathbb{R})$  is defined by

$$\gamma(s, \tau) = \int_{-\infty}^{+\infty} x(t) \psi_{s, \tau}^*(t) dt$$

The inverse wavelet transform is defined by

$$x(t) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \gamma(s, \tau) \psi_{s, \tau} ds d\tau$$

- $\psi(t)$  is the mother wavelet;
- $\psi_{s, \tau}$  is the family of functions  $(s, \tau) \in \mathbb{R}^2$ ;

$$\psi_{s, \tau}(t) = \frac{1}{\sqrt{s}} \psi\left(\frac{t - \tau}{s}\right)$$

- $s$  is the scale parameter,  $\tau$  the translation parameter and  $\frac{1}{\sqrt{s}}$  a normalization factor.

# Definition of the CWT

## Properties:

- To reconstruct the signal without loss of information, the function  $\psi(t)$  must satisfy the admissibility conditions:

$$\int_{\mathbb{R}} \frac{|\hat{\psi}(\omega)|^2}{|\omega|} d\omega < +\infty$$

where,  $\hat{\psi}(\omega)$  is the Fourier transform of  $\psi(t)$ ;

- The admissibility condition implies that

$$|\hat{\psi}(\omega)|^2_{\omega=0} = 0$$

This means that wavelets must have a band-pass like spectrum.

- The CWT is highly redundant (continuously shifting a scalable function over a signal):

a one-dimensional signal  $\xrightarrow{CWT}$  a two-dimensional time-scale joint representation.

$$\gamma(s, \tau) = \int_{-\infty}^{+\infty} x(t) \psi_{s, \tau}^*(t) dt$$

The wavelet transform can be discretized by sampling the time and the scale parameters of a continuous wavelet transform. We must cover the time-frequency space. The goal is to decrease the redundancy (!) of the CWT.

A real continuous wavelet transform of  $x(t)$  is given the function

$$\gamma(s, \tau) = \int_{-\infty}^{+\infty} x(t) \psi_{s, \tau}^*(t) dt$$
$$\psi_{s, \tau}(t) = \frac{1}{\sqrt{s}} \psi\left(\frac{t - \tau}{s}\right)$$

Discrete wavelet family:

$$\psi_{j, n}(t) = \frac{1}{\sqrt{a^j}} \psi\left(\frac{t - n\tau_0 a^j}{a^j}\right), (j, n) \in \mathbb{N} \quad (1)$$

To cover the time-frequency plane with Heisenberg boxes:

- the parameter  $s$  is expressed as  $a^j$  ( $j \in \mathcal{Z}$ ) (sampling);
- The parameter  $\tau$  is sampled uniformly at intervals proportional to the scale  $a^j$ .

When the scale increases, the density of samples increases. Dyadic wavelets are wavelets which satisfy an additional scaling property:  $a = 2$ .

# Scaling function

## Transforms

T. Maugey

What is a transform?

2D Fourier transform

2D Discrete Cosine transform

Wavelet Transform

Graph Transform

Discrete wavelet family:

$$\psi_{j,n}(t) = \frac{1}{\sqrt{a^j}} \psi\left(\frac{t - n\tau_0 a^j}{a^j}\right), (j, n) \in \mathbb{N}$$

To recover  $x(t)$ , we need a complement of information (also true for the CWT).

Every time the wavelet is scaled in the time domain with the factor  $a$ , the frequency bandwidth is halved. It means that you will need an infinite number of wavelets to recover the signal (low-frequencies).

$$\xi(t) = \sum_{j,n} \gamma(j,n) \psi_{j,n}(t)$$

The scaling function  $\xi$  is a signal with a low-pass spectrum.

Note: the scaling function has nothing to do with the scaling parameter.

$$x(t) \xrightarrow{\text{Wavelet serie}} \begin{cases} \lambda_k \\ \gamma(j, n) \end{cases}$$

with,

$$\lambda_k = \int_{-\infty}^{+\infty} x(t)\xi_k^*(t)dt, \text{ low frequencies wavelet coefficients}$$

$$\gamma(j, n) = \int_{-\infty}^{+\infty} x(t)\psi_{j,n}^*(t)dt, \text{ high frequencies wavelet coefficients}$$

The signal  $x(t)$  can be retrieve from the wavelet coefficients

$$x(t) = \sum_k \lambda_k \xi_k(t) + \sum_{j,n} \gamma(j, n) \psi_{j,k}(t)$$

if and only if

- $\xi_k$  and  $\psi_{j,k}$  are an orthogonal basis:

$$\sum_k |\lambda_k|^2 + \sum_{j,n} |\gamma(j, n)|^2 = \|x\|^2$$

- Bi-orthogonal wavelets:  $\xi$  and  $\psi$  are the wavelet used to decompose the signal and we define  $\tilde{\xi}$  and  $\tilde{\psi}$  to reconstruct the signal.

Warning.... Up to now, the input signal was continuous... only the scale and translation parameters were discrete.

The original signal  $x(n)$  passes through two complementary filters and emerges as two signals. The low pass filter is denoted by  $G_0$  while the high pass filter is denoted by  $H_0$ . At each level, the high pass filter produces **detail information**,  $d(n)$ , while the low pass filter associated with scaling function produces **coarse approximations**,  $a(n)$ . Mallat-tree decomposition is shown below:

The DWT uses dyadic scales and positions (scales and positions based on powers of 2).

If we want to define a transform, one needs to take into account the structure behind the data.

**Graphs** represent a pairwise relationship between the entities.

$\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{W})$ , where

- $\mathcal{V}$  are the nodes (indexed from 1 to  $N$ )
- $\mathcal{E}$  are the edges
- $\mathcal{W}$  are the weights on the edges

We define a function  $f$  on the graphs by assigning a value to each node:  $f : \mathcal{V} \rightarrow \mathbb{R}$ .

How to define the transforms on the graph?

In temporal domain, Laplacian operator is defined as

$$\Delta(f(t)) = \frac{\partial^2 f(t)}{\partial t^2}$$

Fourier basis are eigenvectors of the Laplace operator:

$$\Delta(e^{2i\pi\omega t}) = \frac{\partial^2 e^{2i\pi\omega t}}{\partial t^2} = -(2\pi\omega)^2 e^{2i\pi\omega t}$$

Since the Laplacian matrix  $\mathbf{L}$  is positive semi-definite, it can be diagonalized:

$$\mathbf{L} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^\top$$

The orthogonal eigenvectors  $\mathbf{U}$  are defined as the analogy of Fourier Transform on the graph, called **Graph Fourier Transform**.

The eigenvalues  $\lambda_i$  are the analog of the frequencies.

Having a vector  $\mathbf{x}$  of dimension  $N$ .  
A basis change is

$$\mathbf{x} = \mathbf{A}\mathbf{c}.$$

In compression, the goal is to have  $\mathbf{c}$  as sparse as possible.

What if  $\mathbf{A}$  is not an orthogonal basis anymore ?

$\mathbf{A}$  is an over-complete and has dimension  $N \times P$  with  $P > N$ .

$$\mathbf{x} = \mathbf{A}\mathbf{c}.$$

The problem of finding the best dictionary is

$$(\mathbf{c}^*, \mathbf{A}^*) = \arg \min_{\mathbf{c}, \mathbf{A}} \|\mathbf{c}\|_0 \quad \text{s.t.} \quad P < P_{\max} \quad \text{and} \quad \mathbf{A}\mathbf{c} = \mathbf{x}.$$

Non-convex problem, and depends on the application.
