Abstract

The extension of mathematical morphology to color and more generally to multivariate image data is still an open problem. The definition of multivariate morphological operators requires the introduction of a complete lattice structure on the image data, hence vectorial extrema computation methods are necessary. In this paper, we propose a lexicographical approach with this end, based on the principle of $\alpha$-trimming, that leads to flexible, but nevertheless pseudo-morphological operators, in the sense that there is no underlying binary ordering relation among the vectors. Moreover a possible solution to this problem is presented as well as a way of automatically computing the parameter $\alpha$ based on statistical measures. The results of a series of color noise reduction experiments are also included, illustrating the superior performance of the proposed approach against uncorrelated Gaussian noise, with respect to state-of-the-art vector ordering schemes.

1. Introduction

The extension of mathematical morphology to multivariate image data, and specifically to color images is still an open problem. Since the early 1990s, when the underlying theory was formalized [4, 11, 12], and the complete lattice theory was accepted as its appropriate algebraic basis, several approaches were proposed to this end. The requirement of this extension, consisting of a vector ordering that would provide the vectorial extrema necessary for inducing a complete lattice structure on the image data, has led to various multivariate morphological frameworks, of which none has yet been widely accepted. Besides the inherent difficulty of ordering vectorial data, the nature of color has also proven to be an additional obstacle in this regard. A comprehensive survey on the different approaches can be found in [2].

One of the most popular vector ordering mechanisms used in this area is the standard lexicographical approach, which however suffers from the extreme prioritization of the first dimension, hence ignoring largely the rest of the vector components. In this paper, we address this problem, and propose a modified version of lexicographical ordering based on the principle of $\alpha$-trimming, borrowed from the area of noise reduction, where it has been long employed against impulsive noise in the form of the $\alpha$-trimmed mean filter and its variants [9]. Although the resulting $\alpha$-trimmed lexicographical extrema computation scheme provides a more flexible solution with interesting filtering capabilities, we show that the morphological operators thus obtained are theoretically unsound and present a workaround for this problem. We further discuss the choice of the $\alpha$ argument and propose a computation method in this end based on the standard deviation of image channels.

Additionally, the results of a series of tests are provided, where the proposed approach is compared with state-of-the-art vector orderings, in the context of colour noise reduction. Its superior performance against Gaussian noise illustrates its practical interest, in spite of its theoretical deficiencies.

The rest of the paper is organized as follows. Section 2 introduces briefly the theoretical aspects of extending morphological operators to multivariate images and some of the related methodologies. In section 3, the proposed approach is presented and its theoretical properties are elaborated. Then, in section 4, we discuss the results obtained from the comparative tests. Finally section 5 is devoted to concluding remarks.

2. Multivariate Mathematical Morphology

In this section we review briefly the main issues concerning the extension of mathematical morphology to multivariate images. For an in-depth study of this topic the reader can refer to the fundamental references [4, 12].

2.1. Definitions

Among the different methodologies that appeared with the end of extending binary morphological operators to greyscale images, the one based on complete lattices received the widest acceptance and is now considered as the right mathematical framework for morphology [11]. According to this approach, given an image $f : \mathcal{E} \to \mathcal{T}$ with
\[ \mathcal{E} \] an arbitrary non empty set, a complete lattice structure is imposed on the grey-level range \( T \). In other words, \( T \) must be a non empty set equipped with a partial ordering such that every non empty subset \( P \subseteq T \) has a greatest lower bound \( \bigwedge P \) (infimum) and a least upper bound \( \bigvee P \) (supremum). Consequently, while the scalar order is sufficient for verifying this condition in the case of greyscale images, where usually \( T = \mathbb{Z} \) or \( T = \mathbb{R} \), it becomes a much more challenging task with multivariate images, where usually \( T = \mathbb{Z}^m \) or \( T = \mathbb{R}^m \) with \( n > 1 \), since there is no natural ordering relation for multivariate data.

Indeed, given such a vectorial ranking scheme “\( < \)”, the vectorial versions of the two fundamental morphological operators, erosion (\( \epsilon_b \)) and dilation (\( \delta_b \)) of a multivalued image \( f \) by a flat structuring element (SE) \( b \), can be immediately derived by means of the vectorial extrema operators \( \sup_v \) and \( \inf_v \), based on the given ordering:

\[
\epsilon_b(f)(x) = \inf_{s \in b} \{ f(x + s) \} \tag{1}
\]

\[
\delta_b(f)(x) = \sup_{s \in b} \{ f(x - s) \} \tag{2}
\]

Therefore, the main obstacle preventing the extension of morphological operators to multivalued images, consists in defining a vector ordering relation that will induce a complete lattice structure on the image data.

### 2.2. Vector orderings

Vector ordering methodologies have been studied relatively thoroughly in the literature [3], and numerous solutions have been proposed in this end. Some of the most popular of which include the marginal or M-ordering, which is a partial ordering realized in a componentwise fashion, hence neither exploiting the inter-channel relations nor preserving the original vectors. This last property renders marginal ordering inadequate for color images as it introduces false colors. Reduced or R-orderings on the other hand, first reduce vectors into scalar values, and then order them according to the natural scalar order. However, unless the reduction transformation is injective, this approach results in pre-orderings that do not lead necessarily to unique extrema.

**Conditional** or C-orderings, order vectors by means of some of their marginal components, selected sequentially according to different conditions, with the lexicographical ordering “\( <_L \)” being a widely known example of this group:

\[
\forall v, v' \in \mathbb{R}^n, \ v <_L v' \iff \exists i \in \{1, \ldots, n\}, \ (\forall j < i, \ v_j = v'_j) \land (v_i < v'_i) \tag{3}
\]

From a theoretical point of view, lexicographical ordering is a total ordering, thus preserving the input vectors and producing unique extrema. That is why most efforts in the area of multivariate morphology, and color in particular, are based upon it [1, 7].

However, despite its theoretical advantages, most usually in practice the vast majority of lexicographical comparisons are determined by means of the first component [5]. The remaining dimensions hardly participate in this process, hence leading to an inefficient exploitation of the inter-channel relations. In order to remedy this problem, a first attempt was made by Ortiz et al. [8], that proposed the \( \alpha \)-lexicographical ordering:

\[
\forall v, v' \in \mathbb{R}^n, \ v < v' \iff \begin{cases} v_1 + \alpha < v'_1, \ &\text{or} \\ v_1 + \alpha \geq v'_1 \text{ and } [v_2, \ldots, v_n]^T <_L [v'_2, \ldots, v'_n]^T \end{cases} \tag{4}
\]

where \( \alpha \in \mathbb{R} \), and for high values of \( \alpha \), comparisons reach more frequently the second dimension. Nevertheless, expression (4) is not transitive, hence does not represent an ordering from an algebraic point of view. A theoretically more sound methodology was introduced by Angulo [1], the \( \alpha \)-modulus lexicographical ordering:

\[
\forall v, v' \in \mathbb{R}^n, \ v < v' \iff [[v_1/\alpha], v_2, \ldots, v_n]^T <_L [[v'_1/\alpha], v'_2, \ldots, v'_n]^T \tag{5}
\]

which by means of a division by a constant \( \alpha \) followed by a rounding off reduces the dynamic margin of the first component (considered as integer values in \( [0, 255] \)), thus allowing a greater number of comparisons to reach the second.

### 3. \( \alpha \)-trimmed lexicographical extrema

Here, we propose an alternative measure, that can be employed in order to obtain a less “asymmetric” lexicographical ordering, based on the \( \alpha \)-trimming principle used in filters such as the \( \alpha \)-trimmed mean filter (\( \alpha \text{MF} \)) [9]. Given a vector \( v \in \mathbb{R}^n \), containing the sorted scalar pixels under the filtering window, the underlying idea of \( \alpha \)-trimming consists in computing their mean by ignoring the \( 2\alpha \) extreme:

\[
\alpha \text{MF}(v) = \frac{1}{n - 2\alpha} \sum_{i=\alpha+1}^{n-\alpha} v_i \tag{6}
\]

where \( \alpha \in [0, n/2] \), and \( n \) is odd.

### 3.1. Proposed approach

Similarly, in the case of multidimensional vectors we can apply the same principle to each dimension in an iterative fashion. Specifically, in the case of the maximum, starting from the first dimension, we can sort all vectors according to this dimension, and then keep the \( \alpha \) greatest. Consequently, at each step the initial set of vectors will get smaller. Against the eventual situation, where more than one vectors remain at the end of this procedure, we choose to use the last dimension for tie-breaking purposes. A more formal description for computing the maximum based on this procedure, is given in table 1.

As to the minimum, it can be obtained in a likewise fashion by simply sorting in a decreasing order. An illustration of this approach on a three dimensional space \( D_1 \times D_2 \times D_3 \)
is given in figure 1. Of course the value of $\alpha$ greatly influences the choice of extrema. As a matter of fact, with an $\alpha$ approaching zero, from each dimension $i$, only the extreme (i.e. maximum or minimum) vector is kept along with those equal to it with respect to dimension $i$. In other words the procedure becomes identical to the standard lexicographical ordering. On the other hand, when $\alpha$ approaches one, priority is shifted gradually to the last dimension. Additionally, more complicated priority relations among the available channels can be established by means of different $\alpha$ values for each vector dimension.

As far as its computational complexity is concerned, assuming an optimal sorting procedure is used, in the worst scenario, where all $n$ dimensions would need to be sorted, with $k$ vectors the complexity would be in the order of $O(n \times k \times \log k)$. Whereas for the same scenario, the complexity of computing an extremum by means of a lexicographical ordering would be $O(n \times k)$. Besides this additional computational cost, the flexibility of this approach is coupled with an even more important drawback.

Specifically, according to section 2.1, in order to obtain theoretically correct morphological operators, at least a partial ordering needs to be induced on the image data. The proposed extremum computation method however does not have an underlying binary relation, let alone an ordering. All the same, since unique extrema can be computed, the erosion and dilation operators as well as those derived from them can still be defined, however none of the standard morphological properties can be guaranteed (e.g. idempotence, increasingness, etc), hence they are called “pseudo-morphological operators”. A further example of this type of an approach consists of the extrema obtained by cumulative distances, where the minimum is defined as the median vector and the maximum as the most distant. Given $V = \{v_i\}_{1 \leq i \leq k}$ a set of vectors:

$$\max V = \arg \max_i \left\{ \sum_{j \neq i} d(v_i, v_j) \right\}$$  \hspace{1cm} (7)$$

$$\min V = \arg \min_i \left\{ \sum_{j \neq i} d(v_i, v_j) \right\}$$  \hspace{1cm} (8)$$

where $d(\cdot, \cdot)$ denotes a distance.

Although a serious handicap, the lack of an underlying ordering relation does not hinder the practical use of pseudo-morphological operators based on these extremum computation schemes.

For instance Plaza et al. in [10] employ successfully extended morphological profiles calculated using operators based on equations (7) and (8) for the classification of mul-

3.3 Setting

The formal procedure is described in table 2.

Table 2. The ordering of a multi-dimensional space using a set-based minimum computation method
(SetBasedMinimum)

```
Input:
a set V = {v_i}_{1 \leq i \leq k} containing all the vectors of a discrete multi-dimensional space
Output:
the ordered set V' = \{v'_j \in V | \forall m, n \in \{1, \ldots, k\}, m \leq n, v'_m \leq v'_n\} containing the vectors of V
begin
for j = 1 to k
    v'_j = SetBasedMinimum \{V \setminus \{v'_i | i \in \{1, \ldots, k\}, i < j\}\}
    j \leftarrow j + 1
endfor
return V' = \{v'_j\}_{1 \leq j \leq k}
end
```

tispectral remote sensing images. In fact, thanks to the “set-
based” computation of the extrema, conversely to binary rela-
tions, these approaches can be presumed to better exploit
the distribution of the vectors within the multi-dimensional
space, thus often exhibiting interesting behaviors (section 4).

3.2. From set-based to binary relations

Furthermore, in situations where binary orderings are a
necessity, besides using one of the many available alterna-
tives one can also employ the set-based approaches in order
to derive a binary ordering. Specifically, given a discrete
multi-dimensional space, one can employ the set-based ex-
tremum computation method at hand, in order to calculate
the maximum or minimum of this space, and then repeat for
the remaining points, up until the entire space is ordered.
The formal procedure is described in table 2.

Consequently, given then any two vectors within this
space their order is known. Moreover, since \(\alpha\)-trimmed
lexicographical extrema are unique, this type of an ap-
proach would lead to a total ordering. One cannot a pri-
or guess the properties of a such ordering, which would
be radically different depending on the extremum computa-
tion method used (e.g. \(\alpha\)-trimmed lexicographical, cumu-
lative distances, etc) as well as on the extremum employed
(i.e. minimum or maximum). Besides, applying this proce-
dure to the entire vector space would be extremely expen-
tive in terms of computational complexity, but then again
it needs to be done only once. Furthermore, one can also
limit the procedure described in table 2 to the points of the
multi-dimensional space occurring within the image to be
processed, thus obtaining an “image-specific” ordering. Of
course in this case the process needs to be repeated sepa-
ately for every image.

3.3 Setting \(\alpha\)

As mentioned previously in section 3.1, the choice of
\(\alpha\) directly controls the influence of each dimension on the
computed extrema. Besides, finer control can be of course
achieved by using different values of \(\alpha\) for each dimension.
In practice however, it is often necessary to set these argu-
ments in an unsupervised fashion. Here we propose a sim-
ple parameter setting model based on the standard deviation
(\(\sigma\)) of each dimension.

Specifically, if the data are relatively concentrated with
respect to their \(i^{th}\) dimension, or in other words if this im-
age channel does not contain much of the total variational
information, we consider using a large \(\alpha\) to be more per-
tinent, thus decreasing the influence of this dimension by
carrying the majority of the input to the next dimension
with minor trimming. Conversely, if the data are highly dis-
persed with respect to the other dimensions, meaning that
this channel represents relatively important variational in-
formation, a small \(\alpha\) would be used leading to major trim-
ing. Given \(n\) dimensions, one way of obtaining the corre-
sponding \(\alpha_i\) value of dimension \(i\) would be:

\[
\forall i \in \{1, \ldots, n\}, \quad \alpha_i = 1 - \frac{\sigma_i}{\sum_{j=1}^{n} \sigma_j}
\]  

(9)

where \(\sigma_j\) denotes the standard deviation of dimension \(j\).

4. Application: Gaussian noise elimination

In this section, we present the results of comparative tests
carried out with the purpose of both illustrating the practical
advantages of the proposed extrema computation scheme
with respect to state-of-the-art methodologies, as well as as-
serting some of the remarks made in previous sections with
experimental results.

The comparison of ordering approaches in multivariate
mathematical morphology is relatively problematic since
their performance depends on several criteria (e.g. data
space, image data, employed operators, evaluation, etc).
That is why here it was chosen to employ an easily quan-
tifiable task, colour noise reduction, using four images with
varying color distributions (figure 2). Moreover, since lexi-
ocographical ordering in general is most adequate for data
spaces where an inherent priority exists among the dimensions, using the RGB color space, where all three dimensions are equally important, was considered inappropriate. Instead, an intuitive color space based on the notions of hue, saturation and luminance was employed, the improved HLS space based on the max-min norm \([6]\), which remedies important drawbacks of the standard cylindrical HLS space (e.g., dependence between saturation and luminance, etc.).

Since the human vision system is largely known to attribute greater importance to luminance variations with respect to chrominance, it was decided to set the lexicographical comparison order as \(L\) followed by \(S\) and finally \(H\) with respect to chrominance, it was decided to set the lexicographical comparison order as \(L\) followed by \(S\) and finally \(H\). As far as the periodicity of hue is concerned, its ordering was realized in terms of angular distances from a reference hue \(h_0\):

\[
h \div h_0 = \begin{cases} 
|h - h_0| & \text{if } |h - h_0| < 0.5 \\
1 - |h - h_0| & \text{if } |h - h_0| \geq 0.5
\end{cases}
\]

(10)

which for the sake of simplicity was set as \(h_0 = 0.0\). The hue values were then ordered according to their distances from \(h_0\):

\[
\forall h, h' \in [0,1], \quad h < h' \iff h' \div h_0 < h \div h_0
\]

(11)

where hues closer to \(h_0\) are considered greater.

The filtering results are shown in table 3. Judging from the obtained values, the superiority of the marginal approach is obvious. By not being limited with the input vectors it is capable of approximating much better the original image, while the introduction of false colors is also unavoidable. Moreover, we can additionally observe the superiority of luminance over the other two dimensions, hence justifying our choice to set luminance at the first position of the lexicographical comparisons. Furthermore, one can also remark the priority attributed to the first dimension during lexicographical ordering, since its performance is very close to using only luminance. Of the first two \(a\) based approaches only \(a\)-Lex leads to an improvement over Lum, with their difference however not being sufficiently large to draw sound conclusions.

The two trimming based extrema on the other hand, clearly outperform their counterparts. Despite resulting in pseudo-morphological operators, the set based extrema computation is presumed to aid their performance. Furthermore, although the empirically set constant \(a = 0.45\) provides in average the best results, the adaptively set dimension specific arguments exhibit only slightly superior error levels. The image specific \(a\)-trimmed lexicographical ordering however has been disappointing, clearly showing that further work is necessary on this option.

5. Conclusion

The extension of mathematical morphology to multivariate images is a challenging task, due to the ambiguous ordering relations of multidimensional data. Among

the plethora of available ordering approaches, the lexicographical option has been widely experimented with in this regard, as it possesses desirable theoretical properties. In this paper we proposed an alternative solution to its main drawback, the highly asymmetric prioritization of data dimensions. The $\alpha$-trimming principle was used with this purpose, leading to more flexible inter-channel priority relations. Moreover, as with all set based extrema computation schemes lacking an underlying ordering relation, the proposed approach led to pseudo morphological operators, against which an iterative method was proposed in the end of ordering the data space.

The proposed approach was tested against state-of-the-art ordering mechanisms used in color morphology, in the context of Gaussian noise reduction. Despite empirically set arguments for all compared methodologies, $\alpha$-trimming lexicographical extrema outperformed their counterparts, with the proposed adaptive $\alpha$ calculation model also proving to be a robust and unsupervised solution for parameter setting.

Future work will concentrate on the influence of $\alpha$ on applications other than noise reduction (e.g. classification of remote sensing imagery), as well as on more elaborate parametrization models. Moreover, given the relatively high error rates of the $\alpha$-trimmed lexicographical minimum based ordering, possible improvements to the preliminary version of algorithm 2 will be studied.
